

Improved stochastic approximation of regression leverages for bias correction of variance components.

Patrick Kline, Raffaele Saggio, Mikkel Sølvesten

January 21, 2021

This document describes computation of the terms $(P_{ii}, M_{ii}, \sigma_i^2)$ as defined in [Kline, Saggio, and Sølvesten \(2020\)](#) — KSS henceforth — using a variant of the JLA algorithm described in KSS.

There are two closely related ways to estimate $P_{ii} = x_i' S_{xx}^{-1} x_i$ and $M_{ii} = 1 - P_{ii}$ using the random projection algorithm introduced by [Achlioptas \(2003\)](#). Let $q_1, \dots, q_p \in \mathbb{R}^n$ be independent Rademacher vectors with independent entries and construct

$$\hat{P}_{ii} = \frac{1}{p} \sum_{s=1}^p (x_i' S_{xx}^{-1} X' q_s)^2 \quad \text{and} \quad \hat{M}_{ii} = \frac{1}{p} \sum_{s=1}^p (q_{si} - x_i' S_{xx}^{-1} X' q_s)^2$$

which are unbiased estimators of P_{ii} and M_{ii} , respectively. The covariance structure of these two estimators is

$$V(\hat{P}_{ii}) = \frac{2}{p} \left(P_{ii}^2 - \sum_{j=1}^n P_{ij}^4 \right), \quad V(\hat{M}_{ii}) = \frac{2}{p} \left(M_{ii}^2 - \sum_{j=1}^n M_{ij}^4 \right),$$

$$C(\hat{P}_{ii}, \hat{M}_{ii}) = \frac{2}{p} \left(0 - \sum_{j=1}^n P_{ij}^2 M_{ij}^2 \right).$$

When estimating M_{ii} , the infeasible variance minimizing unbiased linear combination of these two estimators is

$$\frac{P_{ii}}{M_{ii} + P_{ii}} \hat{M}_{ii} + \frac{M_{ii}}{M_{ii} + P_{ii}} (1 - \hat{P}_{ii})$$

The feasible version that uses hats everywhere takes a very simple form and is give by

$$\bar{M}_{ii} = \frac{\hat{M}_{ii}}{\hat{M}_{ii} + \hat{P}_{ii}} \tag{1}$$

Remark 1. Note that because \hat{M}_{ii} and \hat{P}_{ii} are both non-negative, we get an estimate that is guaranteed to lie inside $[0, 1]$. The corresponding estimator of P_{ii} is $\bar{P}_{ii} = \frac{\hat{P}_{ii}}{\hat{M}_{ii} + \hat{P}_{ii}}$, so we are simply imposing on the estimators that they satisfy the constraint that $M_{ii} + P_{ii} = 1$. Furthermore, the asymptotic variance (as p gets large) of the constrained estimator \bar{M}_{ii} is

$$V_i = \frac{2}{p} \left(2M_{ii}^2 P_{ii}^2 - (M_{ii} - P_{ii})^2 \sum_{j=1}^n P_{ij}^2 M_{ij}^2 \right).$$

At the boundaries the new estimator has no variance improvement or loss relative to the best of \hat{M}_{ii} and \hat{P}_{ii} , as it simply picks the best of the two. At the center of the support, \hat{M}_{ii} and \hat{P}_{ii} have equal variance and the new estimator improves on both as their correlation is different from -1 . Finally, an inspection of the mean of \bar{M}_{ii} reveals that it relies on shrinkage towards the middle of the support, i.e., the mean of \bar{M}_{ii} (as p gets large) is

$$M_{ii} + B_i, \quad B_i = \frac{2}{p} (P_{ii} - M_{ii}) \left(M_{ii} P_{ii} + 2 \sum_{j=1}^n P_{ij}^2 M_{ij}^2 \right).$$

The estimator highlighted in (1) avoids non-sensical leverage estimates outside of the support, and it reduces variance (thus it allows for fewer repetitions, p , in the JLA algorithm). Furthermore, it does not require extra matrix inversions, as both \hat{M}_{ii} and \hat{P}_{ii} can be constructed after one call to pcg per Rademacher vector.

Non-linearity bias

The JLA approximation of $\hat{\sigma}_i^2 = \frac{y_i(y_i - x_i' \hat{\beta})}{M_{ii}}$ is given by $\tilde{\sigma}_i^2 = \frac{y_i(y_i - x_i' \hat{\beta})}{\bar{M}_{ii}}$. One can see that $\tilde{\sigma}_i^2$ has a mean (conditional on data) approximated to second order that is

$$\hat{\sigma}_i^2 \left(1 + \frac{V_i}{M_{ii}^2} - \frac{B_i}{M_{ii}} \right).$$

We can construct an estimator of the bias using the same Rademacher draws that we use to construct \hat{M}_{ii} and \hat{P}_{ii} and define therefore the following estimator

$$\hat{\sigma}_{i,JLA}^2 = \frac{y_i(y_i - x_i' \hat{\beta})}{\bar{M}_{ii}} \left(1 - \frac{\hat{V}_i}{\bar{M}_{ii}^2} + \frac{\hat{B}_i}{\bar{M}_{ii}} \right).$$

The main advantage of this correction relative to the original one proposed in KSS is that it removes the entire bias of order p^{-1} in the JLA point estimator.¹ We suspect that the next order bias is then of order p^{-2} , thus there is no bias of importance as long as $n/p^4 = o(1)$.

Define the following three second moment estimators

$$m(P_{ii}^2) = \frac{1}{p} \sum_{s=1}^p (x_i' S_{xx}^{-1} X' q_s)^4, \quad m(M_{ii}^2) = \frac{1}{p} \sum_{s=1}^p (q_{si} - x_i' S_{xx}^{-1} X' q_s)^4$$

$$m(P_{ii}, M_{ii}) = \frac{1}{p} \sum_{s=1}^p (x_i' S_{xx}^{-1} X' q_s)^2 (q_{si} - x_i' S_{xx}^{-1} X' q_s)^2.$$

We can then define

$$\hat{V}_i = \frac{1}{p} (\bar{M}_{ii}^2 m(P_{ii}^2) + \bar{P}_{ii}^2 m(M_{ii}^2) - 2\bar{P}_{ii} \bar{M}_{ii} m(P_{ii}, M_{ii}))$$

$$\hat{B}_i = \frac{1}{p} (\bar{M}_{ii} m(P_{ii}^2) - \bar{P}_{ii} m(M_{ii}^2) + (\bar{M}_{ii} - \bar{P}_{ii}) m(P_{ii}, M_{ii})).$$

¹In our experience, based on various simulations and empirical applications, we found that this non-linear bias to show up in small-scale applications where both n and p were relatively small.
